9.2. REPLICATION AND FAILOVER	52
9.3. DISABLING CACHING	53
9.4. CLEARING CACHES AT RUNTIME	53

# CHAPTER 1. GUIDE OVERVIEW

The purpose of this guide is to walk through the steps that need to be completed prior to booting up the Red Hat Single Sign-On server for the first time. If you just want to test drive Red Hat Single Sign-On, it pretty much runs out of the box with its own embedded and local-only database. For actual deployments that are going to be run in production you'll need to decide how you want to manage server configuration at runtime (standalone or domain mode), configure a shared database for Red Hat Single Sign-On storage, set up encryption and HTTPS, and finally set up Red Hat Single Sign-On to run in a cluster. This guide walks through each and every aspect of any pre-boot decisions and setup you must do prior to deploying the server.

One thing to particularly note is that Red Hat Single Sign-On is derived from the JBoss EAP Application Server. Many aspects of configuring Red Hat Single Sign-On revolve around JBoss EAP configuration elements. Often this guide will direct you to documentation outside of the manual if you want to dive into more detail.

## 1.1. RECOMMENDED ADDITIONAL EXTERNAL DOCUMENTATION

Red Hat Single Sign-On is built on top of the JBoss EAP application server and its sub-projects like Infinispan (for caching) and Hibernate (for persistence). This guide only covers basics for infrastructure-level configuration. It is highly recommended that you peruse the documentation for JBoss EAP and its sub projects. Here is the link to the documentation:

✎ [JBoss EAP Configuration Guide](#)

## CHAPTER 2. INSTALLATION

You can install Red Hat Single Sign-On by downloading a ZIP file and unzipping it, or by using an RPM. This chapter reviews system requirements as well as the directory structure.

### 2.1. SYSTEM REQUIREMENTS

These are the requirements to run the Red Hat Single Sign-On authentication server:

- ✦ Can run on any operating system that runs Java
- ✦ Java 8 JDK
- ✦ zip or gzip and tar
- ✦ At least 512M of RAM
- ✦ At least 1G of disk space
- ✦ A shared external database like Postgres, MySql, Oracle, etc. Red Hat Single Sign-On requires an external shared database if you want to run in a cluster. Please see the [database configuration](#) section of this guide for more information.
- ✦ Network multicast support on your machine if you want to run in a cluster. Red Hat Single Sign-On can be clustered without multicast, but this requires a bunch of configuration changes. Please see the [clustering](#) section of this guide for more information.
- ✦ On Linux, it is recommended to use `/dev/urandom` as a source of random data to prevent Red Hat Single Sign-On hanging due to lack of available entropy, unless `/dev/random` usage is mandated by your security policy. To achieve that on Oracle JDK 8 and OpenJDK 8, set the `java.security.egd` system property on startup to `file:/dev/urandom`.

### 2.2. INSTALLING RH-SSO FROM A ZIP FILE

The Red Hat Single Sign-On Server is contained in one distribution file: `rh-sso-7.1.0.zip.gz`.

The `rh-sso-7.1.0.zip.gz` archive is the server-only distribution. It contains only the scripts and binaries to run Red Hat Single Sign-On Server.

To unpack these files, run the `unzip` or `gunzip` utility.

### 2.3. INSTALLING RH-SSO FROM AN RPM

#### Note

With Red Hat Enterprise Linux 7, the term channel was replaced with the term repository. In these instructions only the term repository is used.

You must subscribe to both the JBoss EAP 7.0 and RH-SSO 7.1 repositories before you can install RH-SSO from an RPM.

**Note**

You cannot continue to receive upgrades to EAP 7.0 RPMs but stop receiving updates for RH-SSO.

### 2.3.1. Subscribing to the JBoss EAP 7.0 Repository

#### Prerequisites

1. Ensure that your Red Hat Enterprise Linux system is registered to your account using Red Hat Subscription Manager. For more information see the [Red Hat Subscription Management documentation](#).
2. If you are already subscribed to another JBoss EAP repository, you must unsubscribe from that repository first.

Using Red Hat Subscription Manager, subscribe to the JBoss EAP 7.0 repository using the following command. Replace `<RHEL_VERSION>` with either 6 or 7 depending on your Red Hat Enterprise Linux version.

```
subscription-manager repos --enable=jb-eap-7.0-for-rhel-<RHEL_VERSION>-server-rpms
```

### 2.3.2. Subscribing to the RH-SSO 7.1 Repository and Installing RH-SSO 7.1

#### Prerequisites

1. Ensure that your Red Hat Enterprise Linux system is registered to your account using Red Hat Subscription Manager. For more information see the [Red Hat Subscription Management documentation](#).
2. Ensure that you have already subscribed to the JBoss EAP 7.0 repository. For more information see [Subscribing to the JBoss EAP 7.0 repository](#).

To subscribe to the RH-SSO 7.1 repository and install RH-SSO 7.1, complete the following steps:

1. Using Red Hat Subscription Manager, subscribe to the RH-SSO 7.1 repository using the following command. Replace `<RHEL_VERSION>` with either 6 or 7 depending on your Red Hat Enterprise Linux version.

```
subscription-manager repos --enable=rh-sso-7.1-for-rhel-<RHEL-VERSION>-server-rpms
```

2. Install RH-SSO from your subscribed RH-SSO 7.1 repository using the following command:

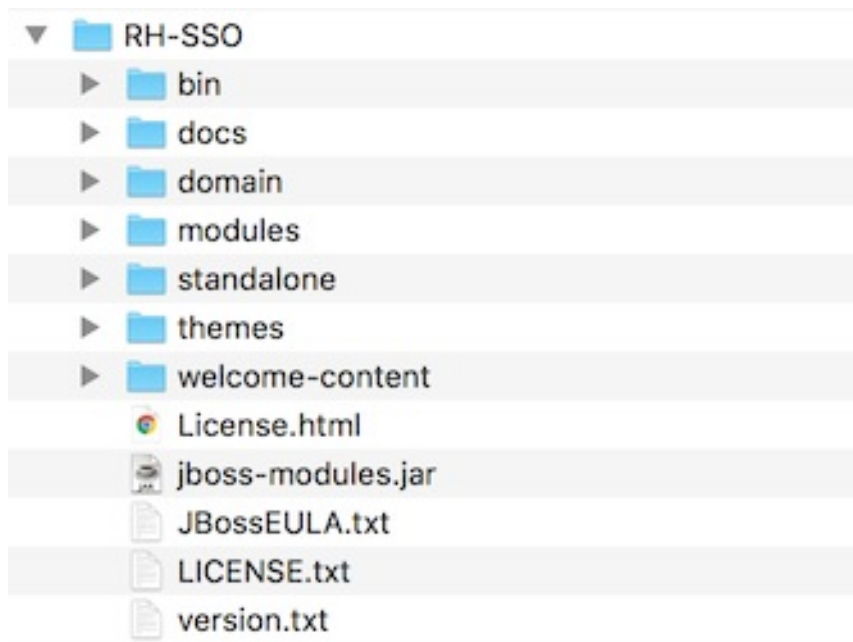

```
yum groupinstall rh-sso7
```

Your installation is complete. The default RH-SSO\_HOME path for the RPM installation is `/opt/rh/rh-sso7/root/usr/share/keycloak`.

## 2.4. DISTRIBUTION DIRECTORY STRUCTURE

This chapter walks you through the directory structure of the server distribution.

## distribution directory structure

Let's examine the purpose of some of the directories:

### ***bin/***

This contains various scripts to either boot the server or perform some other management action on the server.

### ***domain/***

This contains configuration files and working directory when running Red Hat Single Sign-On in [domain mode](#).

### ***modules/***

These are all the Java libraries used by the server.

### ***standalone/***

This contains configuration files and working directory when running Red Hat Single Sign-On in [standalone mode](#).

### ***themes/***

This directory contains all the html, style sheets, javascript files, and images used to display any UI screen displayed by the server. Here you can modify an existing theme or create your own. See the [Server Developer Guide](#) for more information on this.

## CHAPTER 3. CHOOSING AN OPERATING MODE

Before deploying Red Hat Single Sign-On in a production environment you need to decide which type of operating mode you are going to use. Will you run Red Hat Single Sign-On within a cluster? Do you want a centralized way to manage your server configurations? Your choice of operating mode effects how you configure databases, configure caching and even how you boot the server.

### Tip

The Red Hat Single Sign-On is built on top of the JBoss EAP Application Server. This guide will only go over the basics for deployment within a specific mode. If you want specific information on this, a better place to go would be the [JBoss EAP Configuration Guide](#).

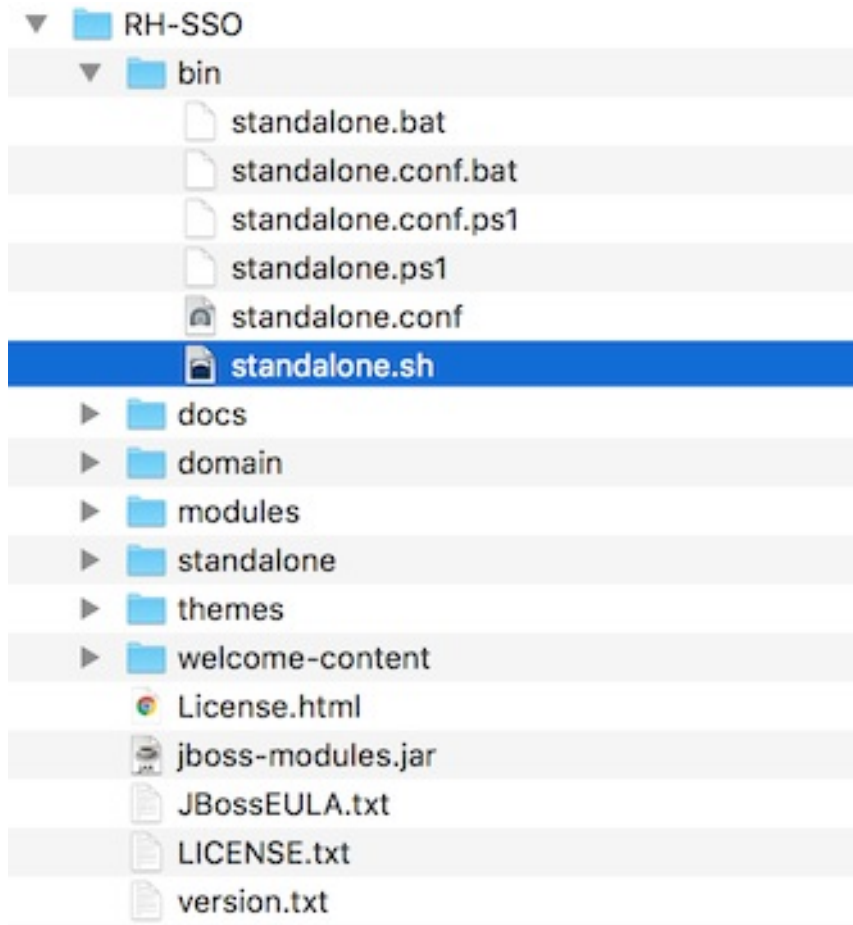

### 3.1. STANDALONE MODE

Standalone operating mode is only useful when you want to run one, and only one Red Hat Single Sign-On server instance. It is not usable for clustered deployments and all caches are non-distributed and local-only. It is not recommended that you use standalone mode in production as you will have a single point of failure. If your standalone mode server goes down, users will not be able to log in. This mode is really only useful to test drive and play with the features of Red Hat Single Sign-On

#### 3.1.1. Standalone Boot Script

When running the server in standalone mode, there is a specific script you need to run to boot the server depending on your operating system. These scripts live in the *bin/* directory of the server distribution.

#### Standalone Boot Scripts

To boot the server:

### Linux/Unix

```
$ .../bin/standalone.sh
```

### Windows

```
> ...\bin\standalone.bat
```

## 3.1.2. Standalone Configuration

The bulk of this guide walks you through how to configure infrastructure level aspects of Red Hat Single Sign-On. These aspects are configured in a configuration file that is specific to the application server that Red Hat Single Sign-On is a derivative of. In the standalone operation mode, this file lives in `.../standalone/configuration/standalone.xml`. This file is also used to configure non-infrastructure level things that are specific to Red Hat Single Sign-On components.

### Standalone Config File

### Warning

Any changes you make to this file while the server is running will not take effect and may even be overwritten by the server. Instead use the the command line scripting or the web console of JBoss EAP. See the [JBoss EAP Configuration Guide](#) for more information.

## 3.2. STANDALONE CLUSTERED MODE

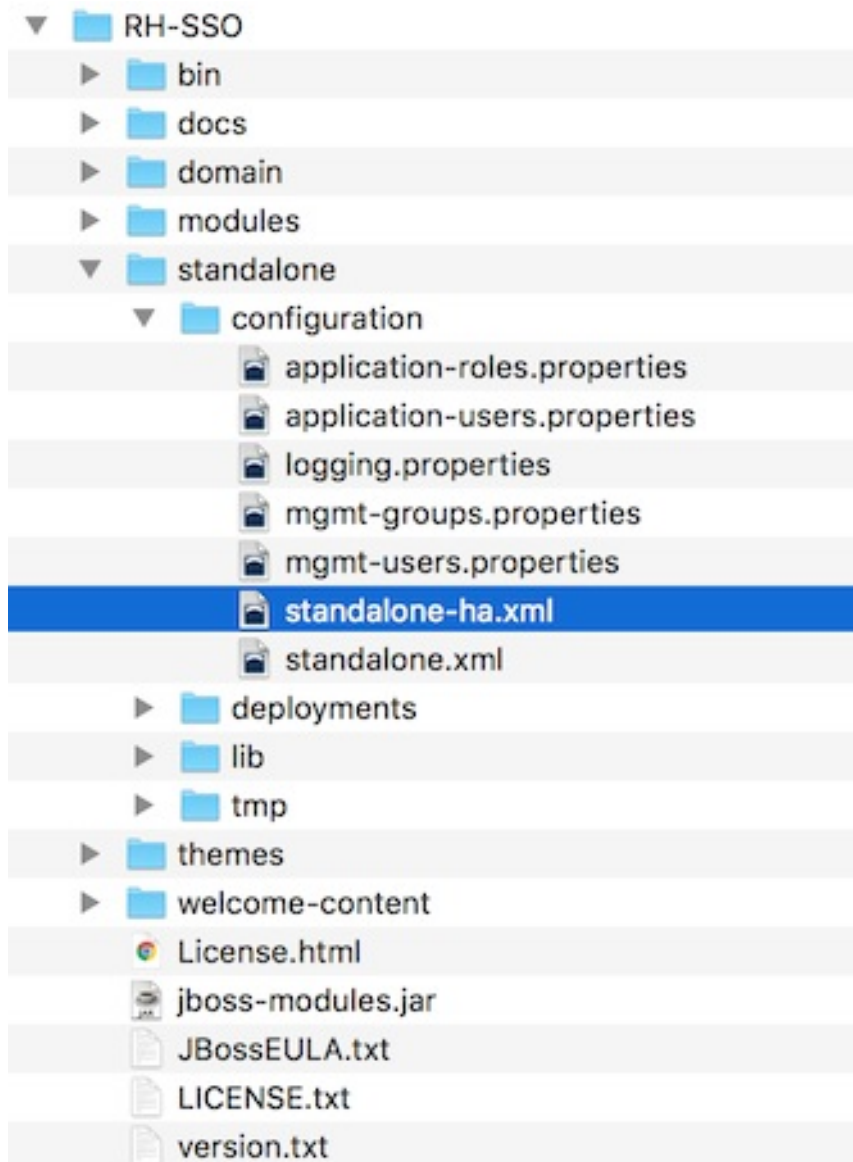

Standalone clustered operation mode is for when you want to run Red Hat Single Sign-On within a cluster. This mode requires that you have a copy of the Red Hat Single Sign-On distribution on each machine you want to run a server instance. This mode can be very easy to deploy initially, but can become quite cumbersome. To make a configuration change you'll have to modify each distribution on each machine. For a large cluster this can become time consuming and error prone.

### 3.2.1. Standalone Clustered Configuration

The distribution has a mostly pre-configured app server configuration file for running within a cluster.

It has all the specific infrastructure settings for networking, databases, caches, and discovery. This file resides in `.../standalone/configuration/standalone-ha.xml`. There's a few things missing from this configuration. You can't run Red Hat Single Sign-On in a cluster without a configuring a shared database connection. You also need to deploy some type of load balancer in front of the cluster. The [clustering](#) and [database](#) sections of this guide walk you through these things.

## Standalone HA Config

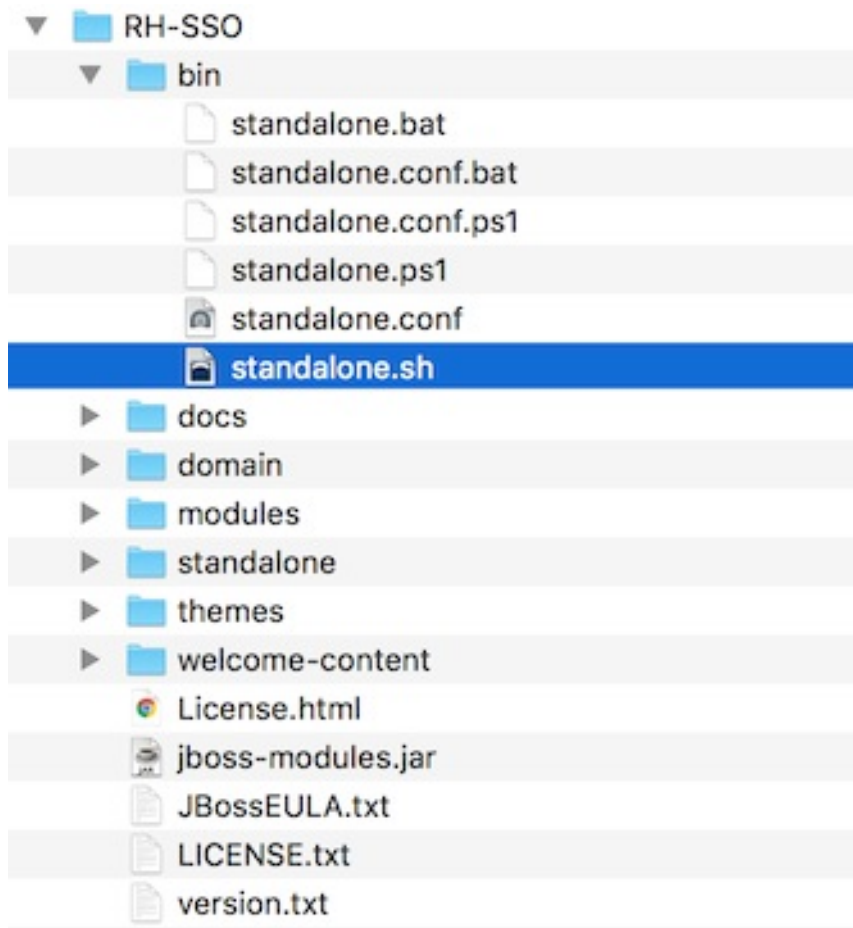

### Warning

Any changes you make to this file while the server is running will not take effect and may even be overwritten by the server. Instead use the the command line scripting or the web console of JBoss EAP. See the [JBoss EAP Configuration Guide](#) for more information.

## 3.2.2. Standalone Clustered Boot Script

You use the same boot scripts to start Red Hat Single Sign-On as you do in standalone mode. The difference is that you pass in an additional flag to point to the HA config file.

## Standalone Clustered Boot Scripts

To boot the server:

### Linux/Unix

```
$ ../bin/standalone.sh --server-config=standalone-ha.xml
```

### Windows

```
> ...\bin\standalone.bat --server-config=standalone-ha.xml
```

## 3.3. DOMAIN CLUSTERED MODE

Domain mode is a way to centrally manage and publish the configuration for your servers.

Running a cluster in standard mode can quickly become aggravating as the cluster grows in size. Every time you need to make a configuration change, you have to perform it on each node in the cluster. Domain mode solves this problem by providing a central place to store and publish configuration. It can be quite complex to set up, but it is worth it in the end. This capability is built into the JBoss EAP Application Server which Red Hat Single Sign-On derives from.

**Note**

The guide will go over the very basics of domain mode. Detailed steps on how to set up domain mode in a cluster should be obtained from the [JBoss EAP Configuration Guide](#).

Here are some of the basic concepts of running in domain mode.

**domain controller**

The domain controller is a process that is responsible for storing, managing, and publishing the general configuration for each node in the cluster. This process is the central point from which nodes in a cluster obtain their configuration.

**host controller**

The host controller is responsible for managing server instances on a specific machine. You configure it to run one or more server instances. The domain controller can also interact with the host controllers on each machine to manage the cluster. To reduce the number of running process, a domain controller also acts as a host controller on the machine it runs on.

**domain profile**

A domain profile is a named set of configuration that can be used by a server to boot from. A domain controller can define multiple domain profiles that are consumed by different servers.

**server group**

A server group is a collection of servers. They are managed and configured as one. You can assign a domain profile to a server group and every service in that group will use that domain profile as their configuration.

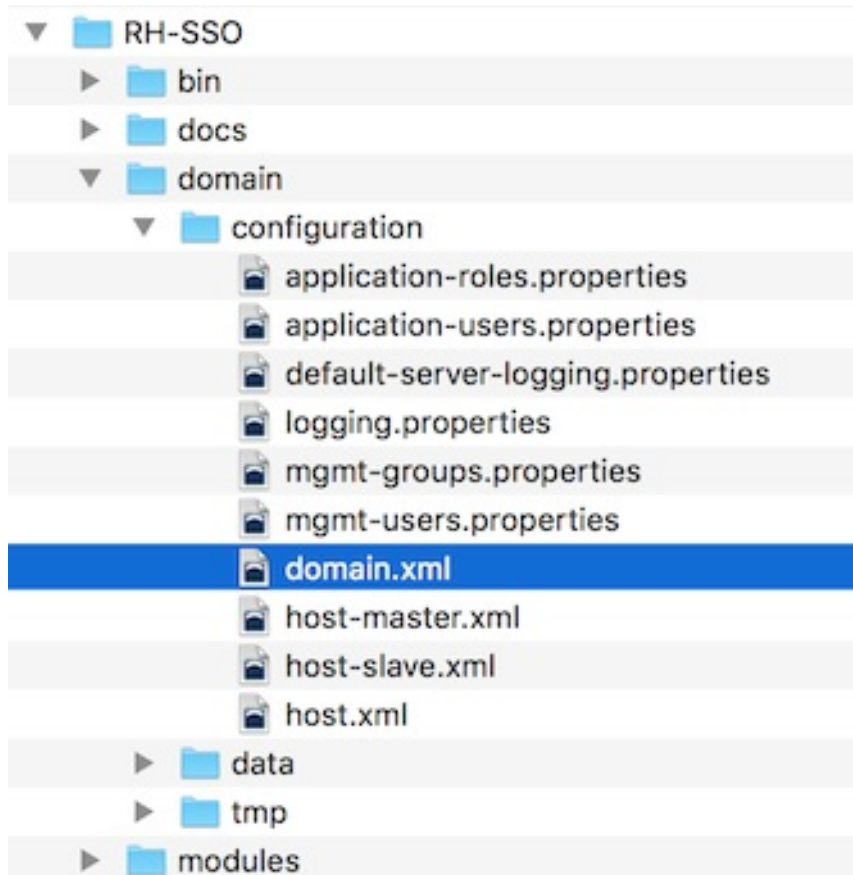

In domain mode, a domain controller is started on a master node. The configuration for the cluster resides in the domain controller. Next a host controller is started on each machine in the cluster. Each host controller deployment configuration specifies how many Red Hat Single Sign-On server instances will be started on that machine. When the host controller boots up, it starts as many Red Hat Single Sign-On server instances as it was configured to do. These server instances pull their configuration from the domain controller.

### 3.3.1. Domain Configuration

Various other chapters in this guide walk you through configuring various aspects like databases, HTTP network connections, caches, and other infrastructure related things. While standalone mode uses the *standalone.xml* file to configure these things, domain mode uses the ...  
*/domain/configuration/domain.xml* configuration file. This is where the domain profile and server group for the Red Hat Single Sign-On server are defined.

**domain.xml**

### Warning

Any changes you make to this file while the domain controller is running will not take effect and may even be overwritten by the server. Instead use the the command line scripting or the web console of JBoss EAP. See the [JBoss EAP Configuration Guide](#) for more information.

Let's look at some aspects of this *domain.xml* file. The **auth-server-standalone** and **auth-server-clustered profile** XML blocks are where you are going to make the bulk of your configuration decisions. You'll be configuring things here like network connections, caches, and database connections.

### auth-server profile

```
<profiles>
  <profile name="auth-server-standalone">
    ...
  </profile>
  <profile name="auth-server-clustered">
    ...
  </profile>
```

The **auth-server-standalone** profile is a non-clustered setup. The **auth-server-clustered** profile is the clustered setup.

If you scroll down further, you'll see various **socket-binding-groups** defined.

## socket-binding-groups

```

<socket-binding-groups>
  <socket-binding-group name="standard-sockets" default-
interface="public">
    ...
  </socket-binding-group>
  <socket-binding-group name="ha-sockets" default-
interface="public">
    ...
  </socket-binding-group>
  <!-- load-balancer-sockets should be removed in production
systems and replaced with a better software or hardware based one -->
  <socket-binding-group name="load-balancer-sockets" default-
interface="public">
    ...
  </socket-binding-group>
</socket-binding-groups>

```

This config defines the default port mappings for various connectors that are opened with each Red Hat Single Sign-On server instance. Any value that contains `${... }` is a value that can be overridden on the command line with the `-D` switch, i.e.

```
$ domain.sh -Djboss.http.port=80
```

The definition of the server group for Red Hat Single Sign-On resides in the **server-groups** XML block. It specifies the domain profile that is used (**default**) and also some default boot arguments for the Java VM when the host controller boots an instance. It also binds a **socket-binding-group** to the server group.

## server group

```

<server-groups>
  <!-- load-balancer-group should be removed in production systems
and replaced with a better software or hardware based one -->
  <server-group name="load-balancer-group" profile="load-balancer">
    <jvm name="default">
      <heap size="64m" max-size="512m"/>
    </jvm>
    <socket-binding-group ref="load-balancer-sockets"/>
  </server-group>
  <server-group name="auth-server-group" profile="auth-server-
clustered">
    <jvm name="default">
      <heap size="64m" max-size="512m"/>
    </jvm>
    <socket-binding-group ref="ha-sockets"/>
  </server-group>
</server-groups>

```

### 3.3.2. Host Controller Configuration

Red Hat Single Sign-On comes with two host controller configuration files that reside in the ...

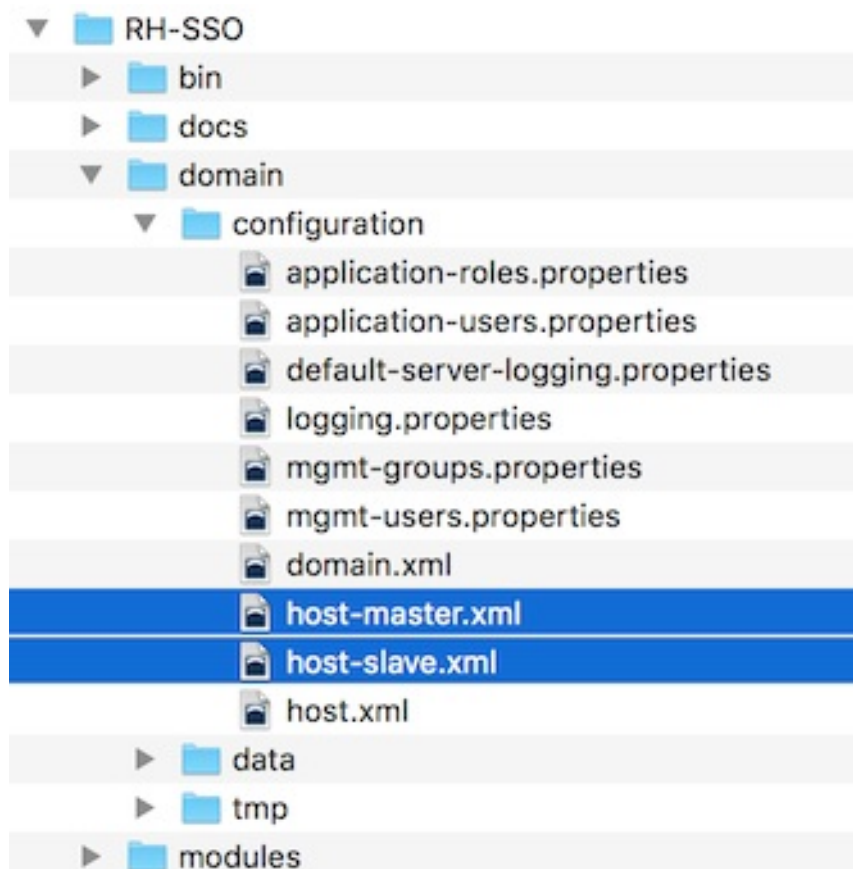

*/domain/configuration/* directory: *host-master.xml* and *host-slave.xml*. *host-master.xml* is configured to boot up a domain controller, a load balancer, and one Red Hat Single Sign-On server instance. *host-slave.xml* is configured to talk to the domain controller and boot up one Red Hat Single Sign-On server instance.

### Note

The load balancer is not a required service. It exists so that you can easily test drive clustering on your development machine. While usable in production, you have the option of replacing it if you have a different hardware or software based load balancer you want to use.

## Host Controller Config

To disable the load balancer server instance, edit *host-master.xml* and comment out or remove the "**load-balancer**" entry.

```
<servers>
  <!-- remove or comment out next line -->
  <server name="load-balancer" group="loadbalancer-group"/>
  ...
</servers>
```

Another interesting thing to note about this file is the declaration of the authentication server instance. It has a **port-offset** setting. Any network port defined in the *domain.xml* **socket-binding-group** or the server group will have the value of **port-offset** added to it. For this example domain setup we do this so that ports opened by the load balancer server don't conflict with the authentication server instance that is started.

```

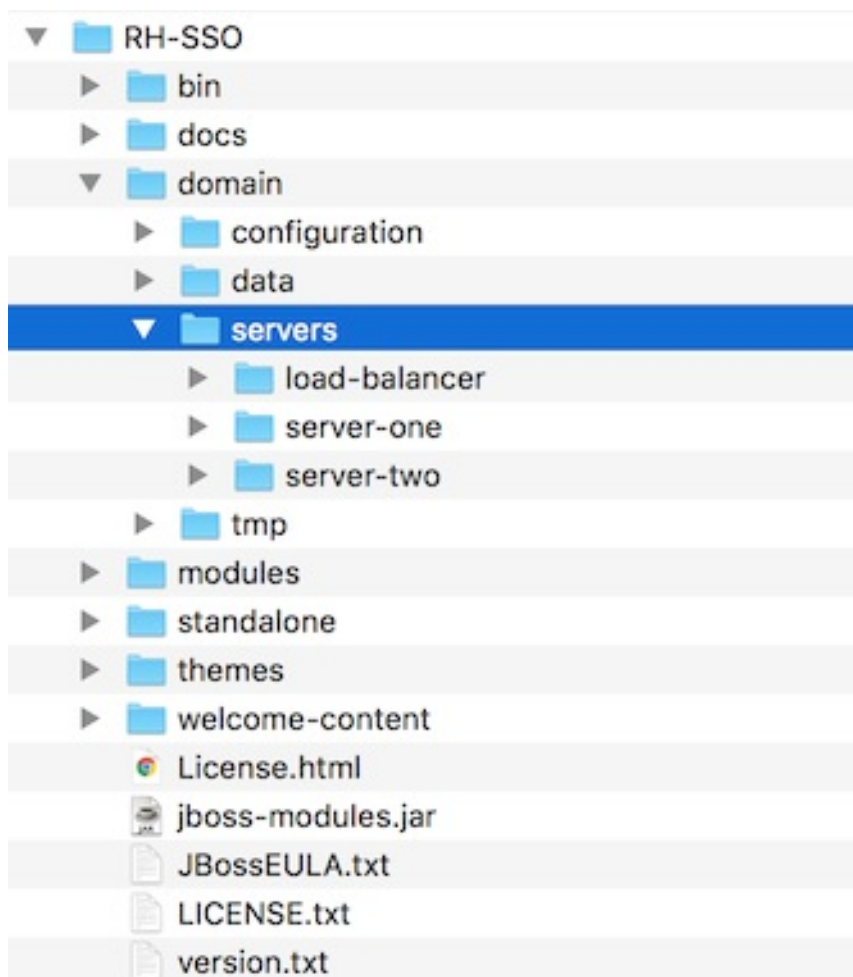

<servers>
  ...
  <server name="server-one" group="auth-server-group" auto-
start="true">
    <socket-bindings port-offset="150"/>
  </server>
</servers>

```

### 3.3.3. Server Instance Working Directories

Each Red Hat Single Sign-On server instance defined in your host files creates a working directory under `.../domain/servers/{SERVER NAME}`. Additional configuration can be put there, and any temporary, log, or data files the server instance needs or creates go there too. The structure of these per server directories ends up looking like any other JBoss EAP booted server.

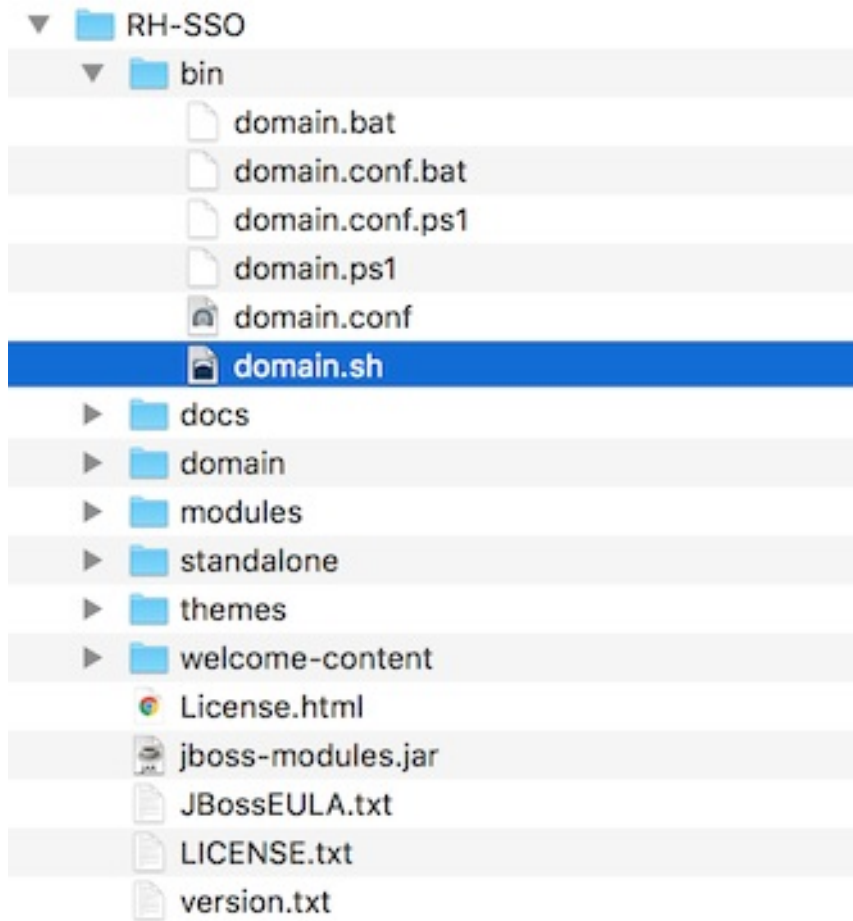

#### Working Directories

### 3.3.4. Domain Boot Script

When running the server in domain mode, there is a specific script you need to run to boot the server depending on your operating system. These scripts live in the `bin/` directory of the server distribution.

#### Domain Boot Script

To boot the server:

### Linux/Unix

```
$ ../bin/domain.sh --host-config=host-master.xml
```

### Windows

```
> ..\bin\domain.bat --host-config=host-slave.xml
```

When running the boot script you will need pass in the host controlling configuration file you are going to use via the **--host-config** switch.

### 3.3.5. Clustered Domain Example

You can test drive clustering using the out-of-the-box *domain.xml* configuration. This example domain is meant to run on one machine and boots up:

- ✎ a domain controller
- ✎ an HTTP load balancer
- ✎ 2 Red Hat Single Sign-On server instances

To simulate running a cluster on two machines, you'll run the `domain.sh` script twice to start two separate host controllers. The first will be the master host controller which will start a domain controller, an HTTP load balancer, and one Red Hat Single Sign-On authentication server instance. The second will be a slave host controller that only starts up an authentication server instance.

### 3.3.5.1. Setup Slave Connection to Domain Controller

Before you can boot things up though, you have to configure the slave host controller so that it can talk securely to the domain controller. If you do not do this, then the slave host will not be able to obtain the centralized configuration from the domain controller. To set up a secure connection, you have to create a server admin user and a secret that will be shared between the master and the slave. You do this by running the `... /bin/add-user.sh` script.

When you run the script select **Management User** and answer **yes** when it asks you if the new user is going to be used for one AS process to connect to another. This will generate a secret that you'll need to cut and paste into the `.../domain/configuration/host-slave.xml` file.

#### Add App Server Admin

```
$ add-user.sh
What type of user do you wish to add?
  a) Management User (mgmt-users.properties)
  b) Application User (application-users.properties)
(a): a
Enter the details of the new user to add.
Using realm 'ManagementRealm' as discovered from the existing property
files.
Username : admin
Password recommendations are listed below. To modify these
restrictions edit the add-user.properties configuration file.
- The password should not be one of the following restricted values
{root, admin, administrator}
- The password should contain at least 8 characters, 1 alphabetic
character(s), 1 digit(s), 1 non-alphanumeric symbol(s)
- The password should be different from the username
Password :
Re-enter Password :
What groups do you want this user to belong to? (Please enter a comma
separated list, or leave blank for none)[ ]:
About to add user 'admin' for realm 'ManagementRealm'
Is this correct yes/no? yes
Added user 'admin' to file './.../standalone/configuration/mgmt-
users.properties'
Added user 'admin' to file './.../domain/configuration/mgmt-
users.properties'
Added user 'admin' with groups to file
 './.../standalone/configuration/mgmt-groups.properties'
Added user 'admin' with groups to file
 './.../domain/configuration/mgmt-groups.properties'
Is this new user going to be used for one AS process to connect to
another AS process?
  e.g. for a slave host controller connecting to the master or for a
```

Remoting connection for server to server EJB calls.

yes/no? yes

To represent the user add the following to the server-identities definition `<secret value="bWdtdDEyMyE=" />`

#### Note

The `add-user.sh` does not add user to Red Hat Single Sign-On server but to the underlying JBoss Enterprise Application Platform. The credentials used and generated in the above script are only for example purpose. Please use the ones generated on your system.

Now cut and paste the secret value into the `.../domain/configuration/host-slave.xml` file as follows:

```
<management>
  <security-realms>
    <security-realm name="ManagementRealm">
      <server-identities>
        <secret value="bWdtdDEyMyE=" />
      </server-identities>
    </security-realm>
  </security-realms>
</management>
```

### 3.3.5.2. Run the Boot Scripts

Since we're simulating a two node cluster on one development machine, you'll run the boot script twice:

#### Boot up master

```
$ domain.sh --host-config=host-master.xml
```

#### Boot up slave

```
$ domain.sh --host-config=host-slave.xml
```

To try it out, open your browser and go to <http://localhost:8080/auth>

## CHAPTER 4. MANAGE SUBSYSTEM CONFIGURATION

Low-level configuration of Red Hat Single Sign-On is done by editing the `standalone.xml`, `standalone-ha.xml`, or `domain.xml` file in your distribution. The location of this file depends on your [operating mode](#).

While there are endless settings you can configure here, this section will focus on configuration of the `keycloak-server` subsystem. No matter which configuration file you are using, configuration of the `keycloak-server` subsystem is the same.

The `keycloak-server` subsystem is typically declared toward the end of the file like this:

```
<subsystem xmlns="urn:jboss:domain:keycloak-server:1.1">
  <web-context>auth</web-context>
  ...
</subsystem>
```

Note that anything changed in this subsystem will not take effect until the server is rebooted.

### 4.1. CONFIGURE SPI PROVIDERS

The specifics of each configuration setting is discussed elsewhere in context with that setting. However, it is useful to understand the format used to declare settings on SPI providers.

Red Hat Single Sign-On is a highly modular system that allows great flexibility. There are more than 50 service provider interfaces (SPIs), and you are allowed to swap out implementations of each SPI. An implementation of an SPI is known as a *provider*.

All elements in an SPI declaration are optional, but a full SPI declaration looks like this:

```
<spi name="myspi">
  <default-provider>myprovider</default-provider>
  <provider name="myprovider" enabled="true">
    <properties>
      <property name="foo" value="bar"/>
    </properties>
  </provider>
  <provider name="mysecondprovider" enabled="true">
    <properties>
      <property name="foo" value="foo"/>
    </properties>
  </provider>
</spi>
```

Here we have two providers defined for the SPI `myspi`. The **default-provider** is listed as **myprovider**. However it is up to the SPI to decide how it will treat this setting. Some SPIs allow more than one provider and some do not. So **default-provider** can help the SPI to choose.

Also notice that each provider defines its own set of configuration properties. The fact that both providers above have a property called **foo** is just a coincidence.

The type of each property value is interpreted by the provider. However, there is one exception. Consider the `jpa` provider for the `eventStore` API:

```
<spi name="eventsStore">
```

```

    <provider name="jpa" enabled="true">
      <properties>
        <property name="exclude-events" value="["&quot;EVENT1&quot;;,
&quot;EVENT2&quot;]"/>
      </properties>
    </provider>
  </spi>

```

We see that the value begins and ends with square brackets. That means that the value will be passed to the provider as a list. In this example, the system will pass the provider a list with two element values *EVENT1* and *EVENT2*. To add more values to the list, just separate each list element with a comma. Unfortunately, you do need to escape the quotes surrounding each list element with `&quot;`.

## 4.2. START THE JBOSS EAP CLI

Besides editing the configuration by hand, you also have the option of changing the configuration by issuing commands via the *jboss-cli* tool. CLI allows you to configure servers locally or remotely. And it is especially useful when combined with scripting.

To start the JBoss EAP CLI, you need to run **jboss-cli**.

### Linux/Unix

```
$ .../bin/jboss-cli.sh
```

### Windows

```
> ...\bin\jboss-cli.bat
```

This will bring you to a prompt like this:

### Prompt

```
[disconnected /]
```

If you wish to execute commands on a running server, you will first execute the **connect** command.

### connect

```
[disconnected /] connect
connect
[standalone@localhost:9990 /]
```

You may be thinking to yourself, "I didn't enter in any username or password!". If you run **jboss-cli** on the same machine as your running standalone server or domain controller and your account has appropriate file permissions, you do not have to setup or enter in a admin username and password. See the *JBoss EAP Configuration Guide* for more details on how to make things more secure if you are uncomfortable with that setup.

### 4.3. CLI EMBEDDED MODE

If you do happen to be on the same machine as your standalone server and you want to issue commands while the server is not active, you can embed the server into CLI and make changes in a special mode that disallows incoming requests. To do this, first execute the **embed** command with the config file you wish to change.

#### embed

```
[disconnected /] embed-server --server-config=standalone.xml  
[standalone@embedded /]
```

### 4.4. CLI GUI MODE

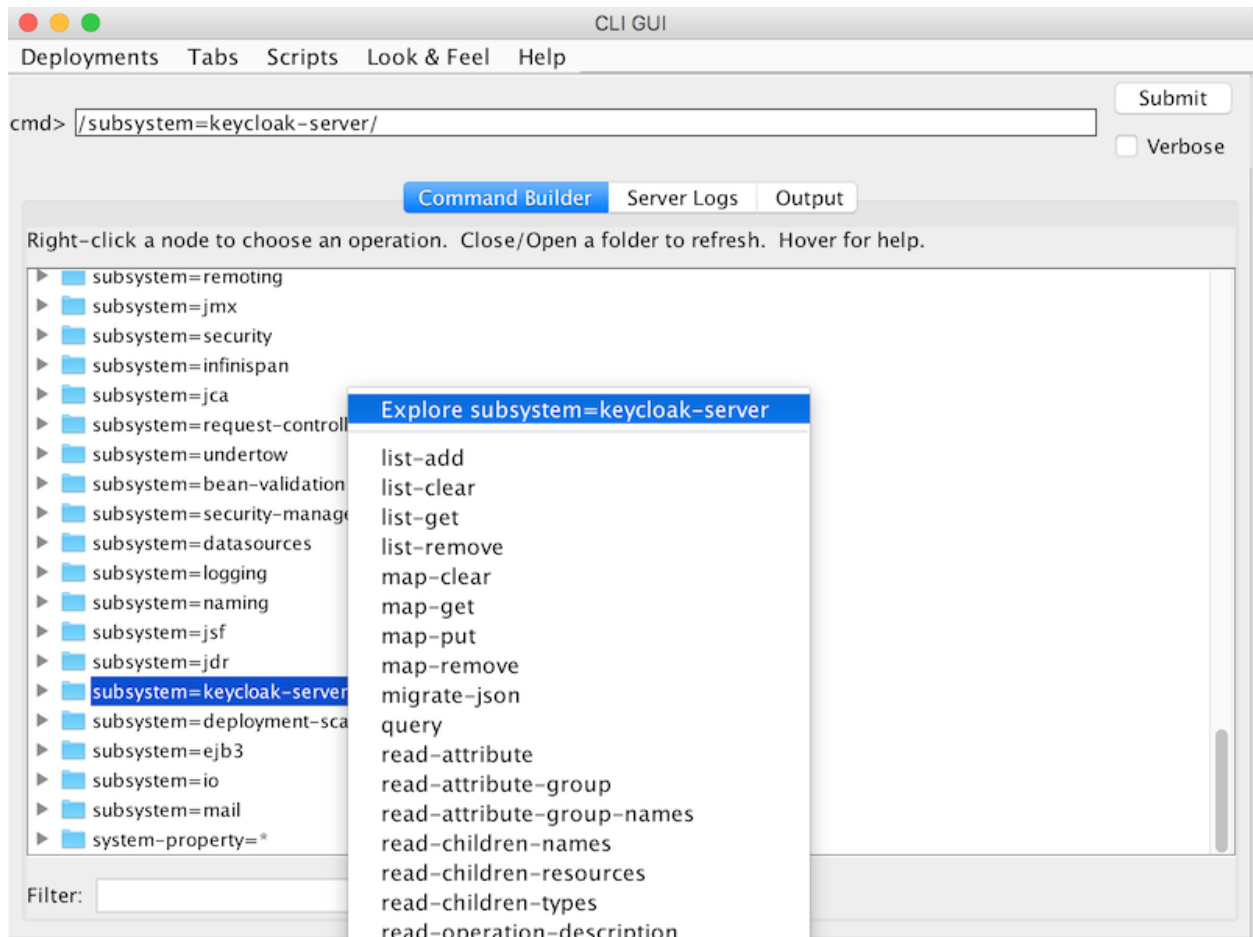

The CLI can also run in GUI mode. GUI mode launches a Swing application that allows you to graphically view and edit the entire management model of a *running* server. GUI mode is especially useful when you need help formatting your CLI commands and learning about the options available. The GUI can also retrieve server logs from a local or remote server.

#### Start in GUI mode

```
$ .../bin/jboss-cli.sh --gui
```

*Note: to connect to a remote server, you pass the **--connect** option as well. Use the **--help** option for more details.*

After launching GUI mode, you will probably want to scroll down to find the node, **subsystem=keycloak-server**. If you right-click on the node and click **Explore subsystem=keycloak-server**, you will get a new tab that shows only the keycloak-server subsystem.

## 4.5. CLI SCRIPTING

The CLI has extensive scripting capabilities. A script is just a text file with CLI commands in it. Consider a simple script that turns off theme and template caching.

### turn-off-caching.cli

```
/subsystem=keycloak-server/theme=defaults/:write-attribute(name=cacheThemes,value=false)
/subsystem=keycloak-server/theme=defaults/:write-attribute(name=cacheTemplates,value=false)
```

To execute the script, I can follow the **Scripts** menu in CLI GUI, or execute the script from the command line as follows:

```
$ ../bin/jboss-cli.sh --file=turn-off-caching.cli
```

## 4.6. CLI RECIPES

Here are some configuration tasks and how to perform them with CLI commands. Note that in all but the first example, we use the wildcard path **\*\*** to mean you should substitute or the path to the keycloak-server subsystem.

For standalone, this just means:

```
** = /subsystem=keycloak-server
```

For domain mode, this would mean something like:

```
** = /profile=auth-server-clustered/subsystem=keycloak-server
```

#### 4.6.1. Change the web context of the server

```
/subsystem=keycloak-server/:write-attribute(name=web-context,value=myContext)
```

#### 4.6.2. Set the global default theme

```
**/theme=defaults/:write-attribute(name=default,value=myTheme)
```

#### 4.6.3. Add a new SPI and a provider

```
**/spi=mySPI/:add  
**/spi=mySPI/provider=myProvider/:add(enabled=true)
```

#### 4.6.4. Disable a provider

```
**/spi=mySPI/provider=myProvider/:write-attribute(name=enabled,value=false)
```

#### 4.6.5. Change the default provider for an SPI

```
**/spi=mySPI/:write-attribute(name=default-provider,value=myProvider)
```

#### 4.6.6. Configure the dblock SPI

```
**/spi=dblock/:add(default-provider=jpa)  
**/spi=dblock/provider=jpa/:add(properties={lockWaitTimeout =>  
"900"},enabled=true)
```

#### 4.6.7. Add or change a single property value for a provider

```
**/spi=dblock/provider=jpa/:map-put(name=properties,key=lockWaitTimeout,value=3)
```

#### 4.6.8. Remove a single property from a provider

```
**/spi=dblock/provider=jpa/:map-remove(name=properties,key=lockRecheckTime)
```

#### 4.6.9. Set values on a provider property of type List

■

```
**/spi=eventsStore/provider=jpa/:map-put(name=properties, key=exclude-  
events, value=[EVENT1, EVENT2])
```

## CHAPTER 5. PROFILES

Red Hat Single Sign-On has two profiles, product and preview. The product profile is enabled by default, which disables some tech preview features. To enable the features you can either switch to the preview profile or enable individual features.

To enable the preview profile start the server with:

```
bin/standalone.sh|bat -Dkeycloak.profile=preview
```

You can set this permanently by creating the file **standalone/configuration/profile.properties** (or **domain/servers/server-one/configuration/profile.properties** for **server-one** in domain mode). Add the following to the file:

```
profile=preview
```

The features that can be enabled and disabled are:

- ✦ Authorization - authorization services
- ✦ Impersonation - ability for admins to impersonate users
- ✦ Script - write custom authenticators using JavaScript

The product profile disables authorization and script.

To disable a specific feature start the server with:

```
bin/standalone.sh|bat -Dkeycloak.profile.feature.<feature name>=disabled
```

For example to disable Impersonation use - **keycloak.profile.feature.impersonation=disabled**.

You can set this permanently in the **profile.properties** file by adding:

```
feature.impersonation=disabled
```

To enable a specific feature without enabling the full preview profile you can start the server with:

```
bin/standalone.sh|bat -Dkeycloak.profile.feature.<feature name>=enabled`
```

For example to enable Authorization Services use - **keycloak.profile.feature.authorization=enabled**.

You can set this permanently in the **profile.properties** file by adding:

```
feature.authorization=enabled
```

## CHAPTER 6. RELATIONAL DATABASE SETUP

Red Hat Single Sign-On comes with its own embedded Java-based relational database called H2. This is the default database that Red Hat Single Sign-On will use to persist data and really only exists so that you can run the authentication server out of the box. We highly recommend that you replace it with a more production ready external database. The H2 database is not very viable in high concurrency situations and should not be used in a cluster either. The purpose of this chapter is to show you how to connect Red Hat Single Sign-On to a more mature database.

Red Hat Single Sign-On uses two layered technologies to persist its relational data. The bottom layered technology is JDBC. JDBC is a Java API that is used to connect to a RDBMS. There are different JDBC drivers per database type that are provided by your database vendor. This chapter discusses how to configure Red Hat Single Sign-On to use one of these vendor-specific drivers.

The top layered technology for persistence is Hibernate JPA. This is a object to relational mapping API that maps Java Objects to relational data. Most deployments of Red Hat Single Sign-On will never have to touch the configuration aspects of Hibernate, but we will discuss how that is done if you run into that rare circumstance.

### Note

Datasource configuration is covered much more thoroughly in [the datasource configuration chapter](#) in the *JBoss EAP Configuration Guide*.

### 6.1. RDBMS SETUP CHECKLIST

These are the steps you will need to perform to get an RDBMS configured for Red Hat Single Sign-On.

1. Locate and download a JDBC driver for your database
2. Package the driver JAR into a module and install this module into the server
3. Declare the JDBC driver in the configuration profile of the server
4. Modify the datasource configuration to use your database's JDBC driver
5. Modify the datasource configuration to define the connection parameters to your database

This chapter will use PostgreSQL for all its examples. Other databases follow the same steps for installation.

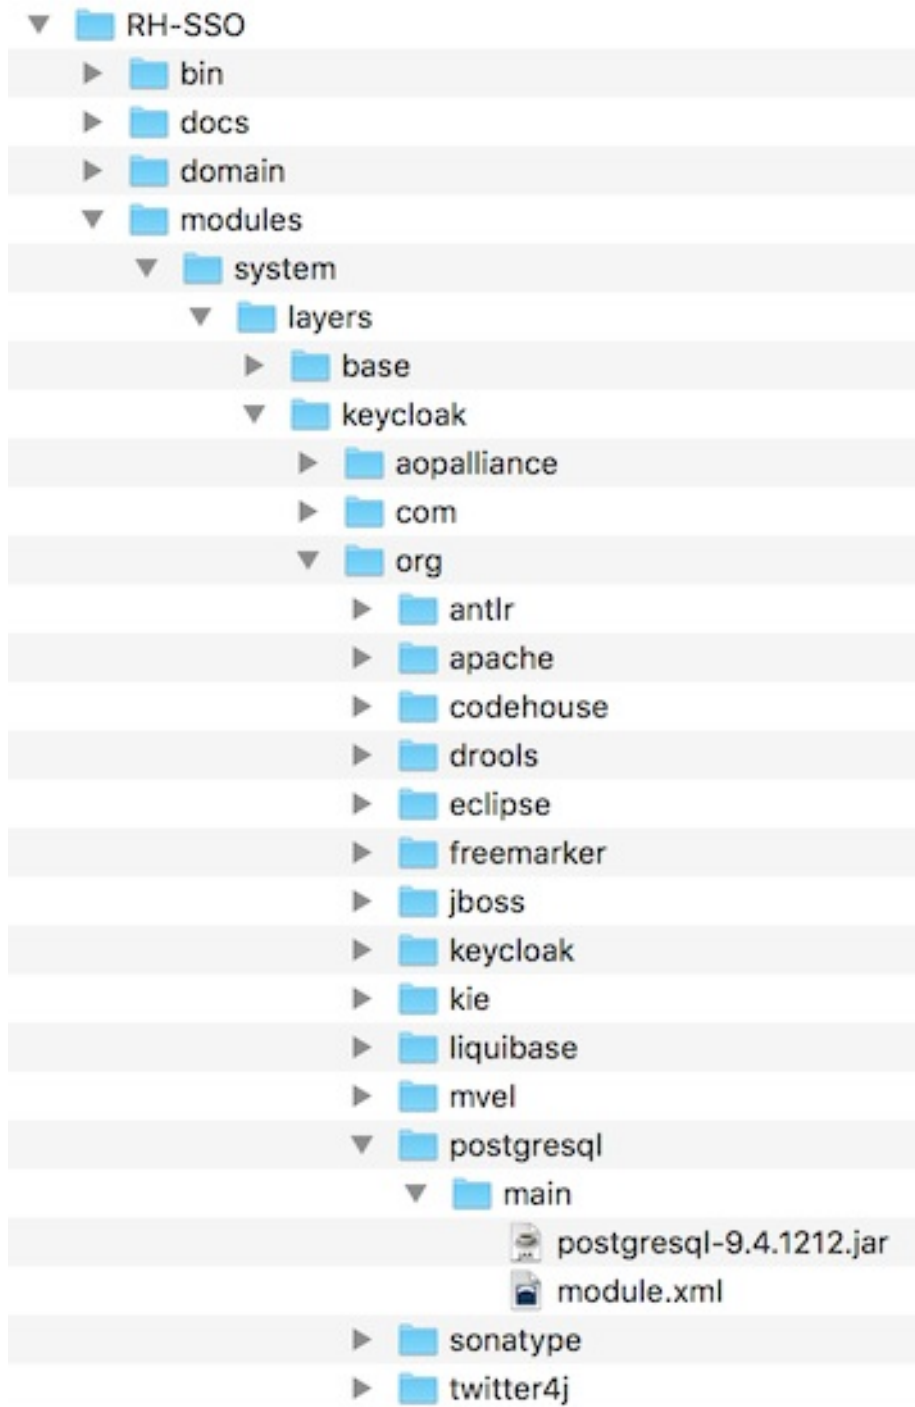

### 6.2. PACKAGE THE JDBC DRIVER

Find and download the JDBC driver JAR for your RDBMS. Before you can use this driver, you must package it up into a module and install it into the server. Modules define JARs that are loaded into the Red Hat Single Sign-On classpath and the dependencies those JARs have on other modules. They are pretty simple to set up.

Within the `.../modules/` directory of your Red Hat Single Sign-On distribution, you need to create a directory structure to hold your module definition. The convention is use the Java package name of the JDBC driver for the name of the directory structure. For PostgreSQL, create the directory `org/postgresql/main`. Copy your database driver JAR into this directory and create an empty

*module.xml* file within it too.

## Module Directory

After you have done this, open up the *module.xml* file and create the following XML:

## Module XML

```

<?xml version="1.0" ?>
<module xmlns="urn:jboss:module:1.3" name="org.postgresql">
  <resources>
    <resource-root path="postgresql-9.4.1212.jar"/>
  </resources>

```

```

<dependencies>
  <module name="javax.api"/>
  <module name="javax.transaction.api"/>
</dependencies>
</module>

```

The module name should match the directory structure of your module. So, *org/postgresql* maps to **org.postgresql**. The **resource-root path** attribute should specify the JAR filename of the driver. The rest are just the normal dependencies that any JDBC driver JAR would have.

### 6.3. DECLARE AND LOAD JDBC DRIVER

The next thing you have to do is declare your newly packaged JDBC driver into your deployment profile so that it loads and becomes available when the server boots up. Where you perform this action depends on your [operating mode](#). If you're deploying in standard mode, edit ... */standalone/configuration/standalone.xml*. If you're deploying in standard clustering mode, edit ... */standalone/configuration/standalone-ha.xml*. If you're deploying in domain mode, edit ... */domain/configuration/domain.xml*. In domain mode, you'll need to make sure you edit the profile you are using: either **auth-server-standalone** or **auth-server-clustered**

Within the profile, search for the **drivers** XML block within the **datasources** subsystem. You should see a pre-defined driver declared for the H2 JDBC driver. This is where you'll declare the JDBC driver for your external database.

#### JDBC Drivers

```

<subsystem xmlns="urn:jboss:domain:datasources:4.0">
  <datasources>
    ...
    <drivers>
      <driver name="h2" module="com.h2database.h2">
        <xa-datasource-class>org.h2.jdbcx.JdbcDataSource</xa-
datasource-class>
      </driver>
    </drivers>
  </datasources>
</subsystem>

```

Within the **drivers** XML block you'll need to declare an additional JDBC driver. It needs to have a **name** which you can choose to be anything you want. You specify the **module** attribute which points to the **module** package you created earlier for the driver JAR. Finally you have to specify the driver's Java class. Here's an example of installing PostgreSQL driver that lives in the module example defined earlier in this chapter.

#### Declare Your JDBC Drivers

```

<subsystem xmlns="urn:jboss:domain:datasources:4.0">
  <datasources>
    ...
    <drivers>
      <driver name="postgresql" module="org.postgresql">
        <xa-datasource-class>org.postgresql.xa.PGXADatasource</xa-
datasource-class>

```

```

        </driver>
        <driver name="h2" module="com.h2database.h2">
            <xa-datasource-class>org.h2.jdbcx.JdbcDataSource</xa-
datasource-class>
        </driver>
    </drivers>
</datasources>
</subsystem>

```

## 6.4. MODIFY THE RED HAT SINGLE SIGN-ON DATASOURCE

After declaring your JDBC driver, you have to modify the existing datasource configuration that Red Hat Single Sign-On uses to connect it to your new external database. You'll do this within the same configuration file and XML block that you registered your JDBC driver in. Here's an example that sets up the connection to your new database:

### Declare Your JDBC Drivers

```

<subsystem xmlns="urn:jboss:domain:datasources:4.0">
    <datasources>
        ...
        <datasource jndi-name="java:jboss/datasources/KeycloakDS" pool-
name="KeycloakDS" enabled="true" use-java-context="true">
            <connection-
url>jdbc:postgresql://localhost/keycloak</connection-url>
            <driver>postgresql</driver>
            <pool>
                <max-pool-size>20</max-pool-size>
            </pool>
            <security>
                <user-name>William</user-name>
                <password>password</password>
            </security>
        </datasource>
        ...
    </datasources>
</subsystem>

```

Search for the **datasource** definition for **KeycloakDS**. You'll first need to modify the **connection-url**. The documentation for your vendor's JDBC implementation should specify the format for this connection URL value.

Next define the **driver** you will use. This is the logical name of the JDBC driver you declared in the previous section of this chapter.

It is expensive to open a new connection to a database every time you want to perform a transaction. To compensate, the datasource implementation maintains a pool of open connections. The **max-pool-size** specifies the maximum number of connections it will pool. You may want to change the value of this depending on the load of your system.

Finally, with PostgreSQL at least, you need to define the database username and password that is needed to connect to the database. You may be worried that this is in clear text in the example. There are methods to obfuscate this, but this is beyond the scope of this guide.

**Note**

For more information about datasource features, see [the datasource configuration chapter](#) in the *JBoss EAP Configuration Guide*.

## 6.5. DATABASE CONFIGURATION

The configuration for this component is found in the `standalone.xml`, `standalone-ha.xml`, or `domain.xml` file in your distribution. The location of this file depends on your [operating mode](#).

### Database Config

```
<subsystem xmlns="urn:jboss:domain:keycloak-server:1.1">
  ...
  <spi name="connectionsJpa">
    <provider name="default" enabled="true">
      <properties>
        <property name="dataSource"
value="java:jboss/datasources/KeycloakDS"/>
        <property name="initializeEmpty" value="false"/>
        <property name="migrationStrategy" value="manual"/>
        <property name="migrationExport"
value="\${jboss.home.dir}/keycloak-database-update.sql"/>
      </properties>
    </provider>
  </spi>
  ...
</subsystem>
```

Possible configuration options are:

#### **dataSource**

JNDI name of the dataSource

#### **jta**

boolean property to specify if datasource is JTA capable

#### **driverDialect**

Value of database dialect. In most cases you don't need to specify this property as dialect will be autodetected by Hibernate.

#### **initializeEmpty**

Initialize database if empty. If set to false the database has to be manually initialized. If you want to manually initialize the database set migrationStrategy to **manual** which will create a file with SQL commands to initialize the database. Defaults to true.

#### **migrationStrategy**

Strategy to use to migrate database. Valid values are **update**, **manual** and **validate**. Update will automatically migrate the database schema. Manual will export the required changes to a file with SQL commands that you can manually execute on the database. Validate will simply check if the database is up-to-date.

**migrationExport**

Path for where to write manual database initialization/migration file.

**showSql**

Specify whether Hibernate should show all SQL commands in the console (false by default). This is very verbose!

**formatSql**

Specify whether Hibernate should format SQL commands (true by default)

**globalStatsInterval**

Will log global statistics from Hibernate about executed DB queries and other things. Statistics are always reported to server log at specified interval (in seconds) and are cleared after each report.

**schema**

Specify the database schema to use

**Note**

These configuration switches and more are described in the [JBoss EAP Development Guide](#).

## 6.6. UNICODE CONSIDERATIONS FOR DATABASES

Database schema in Red Hat Single Sign-On only accounts for Unicode strings in the following special fields:

- ✦ Realms: display name, HTML display name
- ✦ Federation Providers: display name
- ✦ Users: username, given name, last name, attribute names and values
- ✦ Groups: name, attribute names and values
- ✦ Roles: name
- ✦ Descriptions of objects

Otherwise, characters are limited to those contained in database encoding which is often 8-bit. However, for some database systems, it is possible to enable UTF-8 encoding of Unicode characters and use full Unicode character set in all text fields. Often, this is counterbalanced by shorter maximum length of the strings than in case of 8-bit encodings.

Some of the databases require special settings to database and/or JDBC driver to be able to handle Unicode characters. Please find the settings for your database below. Note that if a database is listed here, it can still work properly provided it handles UTF-8 encoding properly both on the level of database and JDBC driver.

Technically, the key criterion for Unicode support for all fields is whether the database allows setting of Unicode character set for **VARCHAR** and **CHAR** fields. If yes, there is a high chance that Unicode will be plausible, usually at the expense of field length. If it only supports Unicode in **NVARCHAR** and **NCHAR** fields, Unicode support for all text fields is unlikely as Keycloak schema uses **VARCHAR** and **CHAR** fields extensively.

### 6.6.1. Oracle Database

Unicode characters are properly handled provided the database was created with Unicode support in **VARCHAR** and **CHAR** fields (e.g. by using **AL32UTF8** character set as the database character set). No special settings is needed for JDBC driver.

If the database character set is not Unicode, then to use Unicode characters in the special fields, the JDBC driver needs to be configured with the connection property **oracle.jdbc.defaultNChar** set to **true**. It might be wise, though not strictly necessary, to also set the **oracle.jdbc.convertNcharLiterals** connection property to **true**. These properties can be set either as system properties or as connection properties. Please note that setting **oracle.jdbc.defaultNChar** may have negative impact on performance. For details, please refer to Oracle JDBC driver configuration documentation.

### 6.6.2. Microsoft SQL Server Database

Unicode characters are properly handled only for the special fields. No special settings of JDBC driver or database is necessary.

### 6.6.3. IBM DB2 Database

Unicode characters are properly handled for all fields, length reduction applies to non-special fields. No special settings of JDBC driver or database is necessary.

### 6.6.4. MySQL Database

Unicode characters are properly handled provided the database was created with Unicode support in **VARCHAR** and **CHAR** fields in the **CREATE DATABASE** command (e.g. by using **utf8** character set as the default database character set in MySQL 5.5. Please note that **utf8mb4** character set does not work due to different storage requirements to **utf8** character set <sup>[1]</sup>). Note that in this case, length restriction to non-special fields does not apply because columns are created to accommodate given amount of characters, not bytes. If the database default character set does not allow storing Unicode, only the special fields allow storing Unicode values.

At the side of JDBC driver settings, it is necessary to add a connection property **characterEncoding=UTF-8** to the JDBC connection settings.

### 6.6.5. PostgreSQL Database

Unicode is supported when the database character set is **UTF8**. In that case, Unicode characters can be used in any field, there is no reduction of field length for non-special fields. No special settings of JDBC driver is necessary.

---

## CHAPTER 7. NETWORK SETUP

Red Hat Single Sign-On can run out of the box with some networking limitations. For one, all network endpoints bind to **localhost** so the auth server is really only usable on one local machine. For HTTP based connections, it does not use default ports like 80 and 443. HTTPS/SSL is not configured out of the box and without it, Red Hat Single Sign-On has many security vulnerabilities. Finally, Red Hat Single Sign-On may often need to make secure SSL and HTTPS connections to external servers and thus need a trust store set up so that endpoints can be validated correctly. This chapter discusses all of these things.

### 7.1. BIND ADDRESSES

By default Red Hat Single Sign-On binds to the localhost loopback address **127.0.0.1**. That's not a very useful default if you want the authentication server available on your network. Generally, what we recommend is that you deploy a reverse proxy or load balancer on a public network and route traffic to individual Red Hat Single Sign-On server instances on a private network. In either case though, you still need to set up your network interfaces to bind to something other than **localhost**.

Setting the bind address is quite easy and can be done on the command line with either the *standalone.sh* or *domain.sh* boot scripts discussed in the [Choosing an Operating Mode](#) chapter.

```
$ standalone.sh -b 192.168.0.5
```

The **-b** switch sets the IP bind address for any public interfaces.

Alternatively, if you don't want to set the bind address at the command line, you can edit the profile configuration of your deployment. Open up the profile configuration file (*standalone.xml* or *domain.xml* depending on your [operating mode](#)) and look for the **interfaces** XML block.

```
<interfaces>
  <interface name="management">
    <inet-address
value="{jboss.bind.address.management:127.0.0.1}"/>
    </interface>
  <interface name="public">
    <inet-address value="{jboss.bind.address:127.0.0.1}"/>
    </interface>
</interfaces>
```

The **public** interface corresponds to subsystems creating sockets that are available publicly. An example of one of these subsystems is the web layer which serves up the authentication endpoints of Red Hat Single Sign-On. The **management** interface corresponds to sockets opened up by the management layer of the JBoss EAP. Specifically the sockets which allow you to use the **jboss-cli.sh** command line interface and the JBoss EAP web console.

In looking at the **public** interface you see that it has a special string **{jboss.bind.address:127.0.0.1}**. This string denotes a value **127.0.0.1** that can be overridden on the command line by setting a Java system property, i.e.:

```
$ domain.sh -Djboss.bind.address=192.168.0.5
```

The **-b** is just a shorthand notation for this command. So, you can either change the bind address value directly in the profile config, or change it on the command line when you boot up.

## Note

There are many more options available when setting up **interface** definitions. For more information, see [the network interface](#) in the *JBoss EAP Configuration Guide*.

## 7.2. SOCKET PORT BINDINGS

The ports opened for each socket have a pre-defined default that can be overridden at the command line or within configuration. To illustrate this configuration, let's pretend you are running in [standalone mode](#) and open up the `.../standalone/configuration/standalone.xml`. Search for **socket-binding-group**.

```
<socket-binding-group name="standard-sockets" default-
interface="public" port-offset="{jboss.socket.binding.port-offset:0}">
  <socket-binding name="management-http" interface="management"
port="{jboss.management.http.port:9990}"/>
  <socket-binding name="management-https" interface="management"
port="{jboss.management.https.port:9993}"/>
  <socket-binding name="ajp" port="{jboss.ajp.port:8009}"/>
  <socket-binding name="http" port="{jboss.http.port:8080}"/>
  <socket-binding name="https" port="{jboss.https.port:8443}"/>
  <socket-binding name="txn-recovery-environment" port="4712"/>
  <socket-binding name="txn-status-manager" port="4713"/>
  <outbound-socket-binding name="mail-smtp">
    <remote-destination host="localhost" port="25"/>
  </outbound-socket-binding>
</socket-binding-group>
```

**socket-bindings** define socket connections that will be opened by the server. These bindings specify the **interface** (bind address) they use as well as what port number they will open. The ones you will be most interested in are:

### http

Defines the port used for Red Hat Single Sign-On HTTP connections

### https

Defines the port used for Red Hat Single Sign-On HTTPS connections

### ajp

This socket binding defines the port used for the AJP protocol. This protocol is used by Apache HTTPD server in conjunction **mod-cluster** when you are using Apache HTTPD as a load balancer.

### management-http

Defines the HTTP connection used by JBoss EAP CLI and web console.

When running in [domain mode](#) setting the socket configurations is a bit trickier as the example `domain.xml` file has multiple **socket-binding-groups** defined. If you scroll down to the **server-group** definitions you can see what **socket-binding-group** is used for each **server-group**.

## domain socket bindings

```

<server-groups>
  <server-group name="load-balancer-group" profile="load-balancer">
    ...
    <socket-binding-group ref="load-balancer-sockets"/>
  </server-group>
  <server-group name="auth-server-group" profile="auth-server-
clustered">
    ...
    <socket-binding-group ref="ha-sockets"/>
  </server-group>
</server-groups>

```

### Note

There are many more options available when setting up **socket-binding-group** definitions. For more information, see [the socket binding group](#) in the *JBoss EAP Configuration Guide*.

## 7.3. SETTING UP HTTPS/SSL

### Warning

Red Hat Single Sign-On is not set up by default to handle SSL/HTTPS. It is highly recommended that you either enable SSL on the Red Hat Single Sign-On server itself or on a reverse proxy in front of the Red Hat Single Sign-On server.

This default behavior is defined by the SSL/HTTPS mode of each Red Hat Single Sign-On realm. This is discussed in more detail in the [Server Administration Guide](#), but let's give some context and a brief overview of these modes.

### external requests

Red Hat Single Sign-On can run out of the box without SSL so long as you stick to private IP addresses like **localhost**, **127.0.0.1**, **10.0.x.x**, **192.168.x.x**, and **172.16.x.x**. If you don't have SSL/HTTPS configured on the server or you try to access Red Hat Single Sign-On over HTTP from a non-private IP address you will get an error.

### none

Red Hat Single Sign-On does not require SSL. This should really only be used in development when you are playing around with things.

### all requests

Red Hat Single Sign-On requires SSL for all IP addresses.

The SSL mode for each realm can be configured in the Red Hat Single Sign-On admin console.

### 7.3.1. Enabling SSL/HTTPS for the Red Hat Single Sign-On Server

If you are not using a reverse proxy or load balancer to handle HTTPS traffic for you, you'll need to enable HTTPS for the Red Hat Single Sign-On server. This involves

1. Obtaining or generating a keystore that contains the private key and certificate for SSL/HTTP traffic
2. Configuring the Red Hat Single Sign-On server to use this keypair and certificate.

### 7.3.1.1. Creating the Certificate and Java Keystore

In order to allow HTTPS connections, you need to obtain a self signed or third-party signed certificate and import it into a Java keystore before you can enable HTTPS in the web container you are deploying the Red Hat Single Sign-On Server to.

#### 7.3.1.1.1. Self Signed Certificate

In development, you will probably not have a third party signed certificate available to test a Red Hat Single Sign-On deployment so you'll need to generate a self-signed one using the **keytool** utility that comes with the Java JDK.

```
$ keytool -genkey -alias localhost -keyalg RSA -keystore keycloak.jks -
validity 10950
  Enter keystore password: secret
  Re-enter new password: secret
  What is your first and last name?
  [Unknown]: localhost
  What is the name of your organizational unit?
  [Unknown]: Keycloak
  What is the name of your organization?
  [Unknown]: Red Hat
  What is the name of your City or Locality?
  [Unknown]: Westford
  What is the name of your State or Province?
  [Unknown]: MA
  What is the two-letter country code for this unit?
  [Unknown]: US
  Is CN=localhost, OU=Keycloak, O=Test, L=Westford, ST=MA, C=US
correct?
  [no]: yes
```

You should answer **What is your first and last name ?** question with the DNS name of the machine you're installing the server on. For testing purposes, **localhost** should be used. After executing this command, the **keycloak.jks** file will be generated in the same directory as you executed the **keytool** command in.

If you want a third-party signed certificate, but don't have one, you can obtain one for free at [cacert.org](https://cacert.org). You'll have to do a little set up first before doing this though.

The first thing to do is generate a Certificate Request:

```
$ keytool -certreq -alias yourdomain -keystore keycloak.jks >
keycloak.careq
```

Where **yourdomain** is a DNS name for which this certificate is generated for. Keytool generates the request:

```

-----BEGIN NEW CERTIFICATE REQUEST-----
MIIC2jCCAcICAQAwwZTELMAkGA1UEBhMCVVMx CzA JBgNVBAgTAK1BMREwDwYDVQQHEwhXZXN

-----END NEW CERTIFICATE REQUEST-----

```

Send this ca request to your CA. The CA will issue you a signed certificate and send it to you. Before you import your new cert, you must obtain and import the root certificate of the CA. You can download the cert from CA (ie.: root.crt) and import as follows:

```
$ keytool -import -keystore keycloak.jks -file root.crt -alias root
```

Last step is to import your new CA generated certificate to your keystore:

```
$ keytool -import -alias yourdomain -keystore keycloak.jks -file your-
certificate.cer
```

### 7.3.1.2. Configure Red Hat Single Sign-On to Use the Keystore

Now that you have a Java keystore with the appropriate certificates, you need to configure your Red Hat Single Sign-On installation to use it. First step is to move the keystore file to the *configuration/* directory of your deployment and to edit the *standalone.xml*, *standalone-ha.xml* or *domain.xml* file to use the keystore and enable HTTPS. (See [operating mode](#)).

In the standalone or domain configuration file, search for the **security-realms** element and add:

```

<security-realm name="UndertowRealm">
  <server-identities>
    <ssl>
      <keystore path="keycloak.jks" relative-

```

```

to="jboss.server.config.dir" keystore-password="secret" />
    </ssl>
  </server-identities>
</security-realm>

```

Find the element **server name="default-server"** (it's a child element of **subsystem xmlns="urn:jboss:domain:undertow:3.1"**) and add:

```

<subsystem xmlns="urn:jboss:domain:undertow:3.1">
  <buffer-cache name="default"/>
  <server name="default-server">
    <https-listener name="https" socket-binding="https" security-
realm="UndertowRealm"/>
    ...
  </server>
</subsystem>

```

## 7.4. OUTGOING HTTP REQUESTS

The Red Hat Single Sign-On server often needs to make non-browser HTTP requests to the applications and services it secures. The auth server manages these outgoing connections by maintaining an HTTP client connection pool. There are some things you'll need to configure in **standalone.xml**, **standalone-ha.xml**, or **domain.xml**. The location of this file depends on your [operating mode](#).

### HTTP client Config example

```

<spi name="connectionsHttpClient">
  <provider name="default" enabled="true">
    <properties>
      <property name="connection-pool-size" value="256"/>
    </properties>
  </provider>
</spi>

```

Possible configuration options are:

#### **establish-connection-timeout-millis**

Timeout for establishing a socket connection.

#### **socket-timeout-millis**

If an outgoing request does not receive data for this amount of time, timeout the connection.

#### **connection-pool-size**

How many connections can be in the pool (128 by default).

#### **max-pooled-per-route**

How many connections can be pooled per host (64 by default).

#### **connection-ttl-millis**

Maximum connection time to live in milliseconds. Not set by default.

**max-connection-idle-time-millis**

Maximum time the connection might stay idle in the connection pool (900 seconds by default). Will start background cleaner thread of Apache HTTP client. Set to **-1** to disable this checking and the background thread.

**disable-cookies**

**true** by default. When set to true, this will disable any cookie caching.

**client-keystore**

This is the file path to a Java keystore file. This keystore contains client certificate for two-way SSL.

**client-keystore-password**

Password for the client keystore. This is *REQUIRED* if **client-keystore** is set.

**client-key-password**

Password for the client's key. This is *REQUIRED* if **client-keystore** is set.

**7.4.1. Outgoing HTTPS Request Truststore**

When Red Hat Single Sign-On invokes on remote HTTPS endpoints, it has to validate the remote server's certificate in order to ensure it is connecting to a trusted server. This is necessary in order to prevent man-in-the-middle attacks. The certificates of these remote server's or the CA that signed these certificates must be put in a truststore. This truststore is managed by the Red Hat Single Sign-On server.

The truststore is used when connecting securely to identity brokers, LDAP identity providers, when sending emails, and for backchannel communication with client applications.

**Warning**

By default, a truststore provider is not configured, and any https connections fall back to standard java truststore configuration as described in [Java's JSSE Reference Guide](#). If there is no trust established, then these outgoing HTTPS requests will fail.

You can use *keytool* to create a new truststore file or add trusted host certificates to an existing one:

```
$ keytool -import -alias HOSTDOMAIN -keystore truststore.jks -file
host-certificate.cer
```

The truststore is configured within the **standalone.xml**, **standalone-ha.xml**, or **domain.xml** file in your distribution. The location of this file depends on your [operating mode](#). You can add your truststore configuration by using the following template:

```
<spi name="truststore">
  <provider name="file" enabled="true">
    <properties>
      <property name="file" value="path to your .jks file
containing public certificates"/>
      <property name="password" value="password"/>
    </properties>
  </provider>
</spi>
```

```
        <property name="hostname-verification-policy"
value="WILDCARD"/>
        <property name="disabled" value="false"/>
    </properties>
</provider>
</spi>
```

Possible configuration options for this setting are:

#### **file**

The path to a Java keystore file. HTTPS requests need a way to verify the host of the server they are talking to. This is what the truststore does. The keystore contains one or more trusted host certificates or certificate authorities. This truststore file should only contain public certificates of your secured hosts. This is *REQUIRED* if **disabled** is not true.

#### **password**

Password for the truststore. This is *REQUIRED* if **disabled** is not true.

#### **hostname-verification-policy**

**WILDCARD** by default. For HTTPS requests, this verifies the hostname of the server's certificate. **ANY** means that the hostname is not verified. **WILDCARD** Allows wildcards in subdomain names i.e. \*.foo.com. **STRICT** CN must match hostname exactly.

#### **disabled**

If true (default value), truststore configuration will be ignored, and certificate checking will fall back to JSSE configuration as described. If set to false, you must configure **file**, and **password** for the truststore.

## CHAPTER 8. CLUSTERING

This section covers configuring Red Hat Single Sign-On to run in a cluster. There's a number of things you have to do when setting up a cluster, specifically:

- ✦ [Pick an operation mode](#)
- ✦ [Configure a shared external database](#)
- ✦ Set up a load balancer
- ✦ Supplying a private network that supports IP multicast

Picking an operation mode and configuring a shared database have been discussed earlier in this guide. In this chapter we'll discuss setting up a load balancer and supplying a private network. We'll also discuss some issues that you need to be aware of when booting up a host in the cluster.

### Note

It is possible to cluster Red Hat Single Sign-On without IP Multicast, but this topic is beyond the scope of this guide. For more information, see [JGroups](#) chapter of the *JBoss EAP Configuration Guide*.

## 8.1. RECOMMENDED NETWORK ARCHITECTURE

The recommended network architecture for deploying Red Hat Single Sign-On is to set up an HTTP/HTTPS load balancer on a public IP address that routes requests to Red Hat Single Sign-On servers sitting on a private network. This isolates all clustering connections and provides a nice means of protecting the servers.

### Note

By default, there is nothing to prevent unauthorized nodes from joining the cluster and broadcasting multicast messages. This is why cluster nodes should be in a private network, with a firewall protecting them from outside attacks.

## 8.2. CLUSTERING EXAMPLE

Red Hat Single Sign-On does come with an out of the box clustering demo that leverages domain mode. Review the [Clustered Domain Example](#) chapter for more details.

## 8.3. SETTING UP A LOAD BALANCER OR PROXY

This section discusses a number of things you need to configure before you can put a reverse proxy or load balancer in front of your clustered Red Hat Single Sign-On deployment. It also covers configuring the built in load balancer that was [Clustered Domain Example](#).

### 8.3.1. Identifying Client IP Addresses

A few features in Red Hat Single Sign-On rely on the fact that the remote address of the HTTP client connecting to the authentication server is the real IP address of the client machine. Examples include:

- ✦ Event logs - a failed login attempt would be logged with the wrong source IP address
- ✦ SSL required - if the SSL required is set to external (the default) it should require SSL for all external requests
- ✦ Authentication flows - a custom authentication flow that uses the IP address to for example show OTP only for external requests
- ✦ Dynamic Client Registration

This can be problematic when you have a reverse proxy or loadbalancer in front of your Red Hat Single Sign-On authentication server. The usual setup is that you have a frontend proxy sitting on a public network that load balances and forwards requests to backend Red Hat Single Sign-On server instances located in a private network. There is some extra configuration you have to do in this scenario so that the actual client IP address is forwarded to and processed by the Red Hat Single Sign-On server instances. Specifically:

- ✦ Configure your reverse proxy or loadbalancer to properly set **X-Forwarded-For** and **X-Forwarded-Proto** HTTP headers.
- ✦ Configure your reverse proxy or loadbalancer to preserve the original 'Host' HTTP header.
- ✦ Configure the authentication server to read the client's IP address from **X-Forwarded-For header**.

Configuring your proxy to generate the **X-Forwarded-For** and **X-Forwarded-Proto** HTTP headers and preserving the original **Host** HTTP header is beyond the scope of this guide. Take extra precautions to ensure that the **X-Forwarded-For** header is set by your proxy. If your proxy isn't configured correctly, then *rogue* clients can set this header themselves and trick Red Hat Single Sign-On into thinking the client is connecting from a different IP address than it actually is. This becomes really important if you are doing any black or white listing of IP addresses.

Beyond the proxy itself, there are a few things you need to configure on the Red Hat Single Sign-On side of things. If your proxy is forwarding requests via the HTTP protocol, then you need to configure Red Hat Single Sign-On to pull the client's IP address from the **X-Forwarded-For** header rather than from the network packet. To do this, open up the profile configuration file (*standalone.xml*, *standalone-ha.xml*, or *domain.xml* depending on your [operating mode](#)) and look for the **urn:jboss:domain:undertow:3.1** XML block.

### X-Forwarded-For HTTP Config

```
<subsystem xmlns="urn:jboss:domain:undertow:3.1">
  <buffer-cache name="default"/>
  <server name="default-server">
    <ajp-listener name="ajp" socket-binding="ajp"/>
    <http-listener name="default" socket-binding="http" redirect-
socket="https"
      proxy-address-forwarding="true"/>
    ...
  </server>
  ...
</subsystem>
```

Add the **proxy-address-forwarding** attribute to the **http-listener** element. Set the value to **true**.

If your proxy is using the AJP protocol instead of HTTP to forward requests (i.e. Apache HTTPD + mod-cluster), then you have to configure things a little differently. Instead of modifying the **http-listener**, you need to add a filter to pull this information from the AJP packets.

### X-Forwarded-For AJP Config

```
<subsystem xmlns="urn:jboss:domain:undertow:3.1">
  <buffer-cache name="default"/>
  <server name="default-server">
    <ajp-listener name="ajp" socket-binding="ajp"/>
    <http-listener name="default" socket-binding="http" redirect-
socket="https"/>
    <host name="default-host" alias="localhost">
      ...
      <filter-ref name="proxy-peer"/>
    </host>
  </server>
  ...
  <filters>
    ...
    <filter name="proxy-peer"
      class-
name="io.undertow.server.handlers.ProxyPeerAddressHandler"
      module="io.undertow.core" />
  </filters>
</subsystem>
```

### 8.3.2. Enable HTTPS/SSL with a Reverse Proxy

Assuming that your reverse proxy doesn't use port 8443 for SSL you also need to configure what port HTTPS traffic is redirected to.

```
<subsystem xmlns="urn:jboss:domain:undertow:3.1">
  ...
  <http-listener name="default" socket-binding="http"
    proxy-address-forwarding="true" redirect-socket="proxy-https"/>
  ...
</subsystem>
```

Add the **redirect-socket** attribute to the **http-listener** element. The value should be **proxy-https** which points to a socket binding you also need to define.

Then add a new **socket-binding** element to the **socket-binding-group** element:

```
<socket-binding-group name="standard-sockets" default-interface="public"
  port-offset="{jboss.socket.binding.port-offset:0}">
  ...
  <socket-binding name="proxy-https" port="443"/>
  ...
</socket-binding-group>
```

### 8.3.3. Verify Configuration

You can verify the reverse proxy or load balancer configuration by opening the path `/auth/realms/master/.well-known/openid-configuration` through the reverse proxy. For example if the reverse proxy address is `https://acme.com/` then open the URL `https://acme.com/auth/realms/master/.well-known/openid-configuration`. This will show a JSON document listing a number of endpoints for Red Hat Single Sign-On. Make sure the endpoints starts with the address (scheme, domain and port) of your reverse proxy or load balancer. By doing this you make sure that Red Hat Single Sign-On is using the correct endpoint.

You should also verify that Red Hat Single Sign-On sees the correct source IP address for requests. Do check this you can try to login to the admin console with an invalid username and/or password. This should show a warning in the server log something like this:

```
08:14:21,287 WARN  XNIO-1 task-45 [org.keycloak.events]
type=LOGIN_ERROR, realmId=master, clientId=security-admin-console,
userId=8f20d7ba-4974-4811-a695-242c8fbd1bf8, ipAddress=X.X.X.X,
error=invalid_user_credentials, auth_method=openid-connect,
auth_type=code,
redirect_uri=http://localhost:8080/auth/admin/master/console/?
redirect_fragment=%2Frealms%2Fmaster%2Fevents-settings,
code_id=a3d48b67-a439-4546-b992-e93311d6493e, username=admin
```

Check that the value of `ipAddress` is the IP address of the machine you tried to login with and not the IP address of the reverse proxy or load balancer.

### 8.3.4. Using the Built-In Load Balancer

This section covers configuring the built in load balancer that is discussed in the [Clustered Domain Example](#).

The [Clustered Domain Example](#) is only designed to run on one machine. To bring up a slave on another host, you'll need to

1. Edit the `domain.xml` file to point to your new host slave
2. Copy the server distribution. You don't need the `domain.xml`, `host.xml`, or `host-master.xml` files. Nor do you need the `standalone/` directory.
3. Edit the `host-slave.xml` file to change the bind addresses used or override them on the command line

#### 8.3.4.1. Register a New Host With Load Balancer

Let's look first at registering the new host slave with the load balancer configuration in `domain.xml`. Open this file and go to the undertow configuration in the **load-balancer** profile. Add a new **host** definition called **remote-host3** within the **reverse-proxy** XML block.

#### domain.xml reverse-proxy config

```
<subsystem xmlns="urn:jboss:domain:undertow:3.1">
  ...
  <handlers>
    <reverse-proxy name="lb-handler">
```

```

        <host name="host1" outbound-socket-binding="remote-host1"
scheme="ajp" path="/" instance-id="myroute1"/>
        <host name="host2" outbound-socket-binding="remote-host2"
scheme="ajp" path="/" instance-id="myroute2"/>
        <host name="remote-host3" outbound-socket-binding="remote-host3"
scheme="ajp" path="/" instance-id="myroute3"/>
    </reverse-proxy>
</handlers>
...
</subsystem>

```

The **output-socket-binding** is a logical name pointing to a **socket-binding** configured later in the *domain.xml* file. the **instance-id** attribute must also be unique to the new host as this value is used by a cookie to enable sticky sessions when load balancing.

Next go down to the **load-balancer-sockets socket-binding-group** and add the **outbound-socket-binding** for **remote-host3**. This new binding needs to point to the host and port of the new host.

### domain.xml outbound-socket-binding

```

<socket-binding-group name="load-balancer-sockets" default-
interface="public">
    ...
    <outbound-socket-binding name="remote-host1">
        <remote-destination host="localhost" port="8159"/>
    </outbound-socket-binding>
    <outbound-socket-binding name="remote-host2">
        <remote-destination host="localhost" port="8259"/>
    </outbound-socket-binding>
    <outbound-socket-binding name="remote-host3">
        <remote-destination host="192.168.0.5" port="8259"/>
    </outbound-socket-binding>
</socket-binding-group>

```

#### 8.3.4.2. Master Bind Addresses

Next thing you'll have to do is to change the **public** and **management** bind addresses for the master host. Either edit the *domain.xml* file as discussed in the [Bind Addresses](#) chapter or specify these bind addresses on the command line as follows:

```

$ domain.sh --host-config=host-master.xml -
Djboss.bind.address=192.168.0.2 -
Djboss.bind.address.management=192.168.0.2

```

#### 8.3.4.3. Host Slave Bind Addresses

Next you'll have to change the **public**, **management**, and domain controller bind addresses (**jboss.domain.master-address**). Either edit the *host-slave.xml* file or specify them on the command line as follows:

```
$ domain.sh --host-config=host-slave.xml
-Djboss.bind.address=192.168.0.5
-Djboss.bind.address.management=192.168.0.5
-Djboss.domain.master.address=192.168.0.2
```

The values of `jboss.bind.address` and `jboss.bind.address.management` pertain to the host slave's IP address. The value of `jboss.domain.master.address` need to be the IP address of the domain controller which is the management address of the master host.

### 8.3.5. Configuring Other Load Balancers

See [the load balancing](#) section in the *JBoss EAP Configuration Guide* for information how to use other software-based load balancers.

## 8.4. MULTICAST NETWORK SETUP

Out of the box clustering support has a need to for IP Multicast. Multicast is a network broadcast protocol. This protocol is used at boot time to discover and join the cluster. It is also used to broadcast messages for the replication and invalidation distributed caches used by Red Hat Single Sign-On.

The clustering subsystem for Red Hat Single Sign-On runs on the JGroups stack. Out of the box, the bind addresses for clustering are bound to a private network interface with a default IP address of 127.0.0.1. You'll have to edit your the `standalone-ha.xml` or `domain.xml` sections discussed in the [Bind Address](#) chapter.

### private network config

```
<interfaces>
  ...
  <interface name="private">
    <inet-address
value="{jboss.bind.address.private:127.0.0.1}"/>
    </interface>
  </interfaces>
  <socket-binding-group name="standard-sockets" default-
interface="public" port-offset="{jboss.socket.binding.port-offset:0}">
    ...
    <socket-binding name="jgroups-mping" interface="private" port="0"
multicast-address="{jboss.default.multicast.address:230.0.0.4}"
multicast-port="45700"/>
    <socket-binding name="jgroups-tcp" interface="private"
port="7600"/>
    <socket-binding name="jgroups-tcp-fd" interface="private"
port="57600"/>
    <socket-binding name="jgroups-udp" interface="private"
port="55200" multicast-
address="{jboss.default.multicast.address:230.0.0.4}" multicast-
port="45688"/>
    <socket-binding name="jgroups-udp-fd" interface="private"
port="54200"/>
```

```

        <socket-binding name="modcluster" port="0" multicast-
address="224.0.1.105" multicast-port="23364"/>
        ...
    </socket-binding-group>

```

Things you'll want to configure are the `jboss.bind.address.private` and `jboss.default.multicast.address` as well as the ports of the services on the clustering stack.

#### Note

It is possible to cluster Red Hat Single Sign-On without IP Multicast, but this topic is beyond the scope of this guide. For more information, see [JGroups](#) in the *JBoss EAP Configuration Guide*.

## 8.5. SECURING CLUSTER COMMUNICATION

When cluster nodes are isolated on a private network it requires access to the private network to be able to join a cluster or to view communication in the cluster. In addition you can also enable authentication and encryption for cluster communication. As long as your private network is secure it is not necessary to enable authentication and encryption. Red Hat Single Sign-On does not send very sensitive information on the cluster in either case.

If you want to enable authentication and encryption for clustering communication see [Securing a Cluster](#) in the *JBoss EAP Configuration Guide*.

## 8.6. SERIALIZED CLUSTER STARTUP

Red Hat Single Sign-On cluster nodes are allowed to boot concurrently. When Red Hat Single Sign-On server instance boots up it may do some database migration, importing, or first time initializations. A DB lock is used to prevent start actions from conflicting with one another when cluster nodes boot up concurrently.

By default, the maximum timeout for this lock is 900 seconds. If a node is waiting on this lock for more than the timeout it will fail to boot. Typically you won't need to increase/decrease the default value, but just in case it's possible to configure it in `standalone.xml`, `standalone-ha.xml`, or `domain.xml` file in your distribution. The location of this file depends on your [operating mode](#).

```

<spi name="dblock">
  <provider name="jpa" enabled="true">
    <properties>
      <property name="lockWaitTimeout" value="900"/>
    </properties>
  </provider>
</spi>

```

## 8.7. BOOTING THE CLUSTER

Booting Red Hat Single Sign-On in a cluster depends on your [operating mode](#)

### Standalone Mode

```
$ bin/standalone.sh --server-config=standalone-ha.xml
```

## Domain Mode

```
$ bin/domain.sh --host-config=host-master.xml  
$ bin/domain.sh --host-config=host-slave.xml
```

## 8.8. TROUBLESHOOTING

Note that when you run cluster, you should see message similar to this in the log of both cluster nodes:

```
INFO [org.infinispan.remoting.transport.jgroups.JGroupsTransport]  
(Incoming-10,shared=udp)  
ISPN000094: Received new cluster view: [node1/keycloak|1] (2)  
[node1/keycloak, node2/keycloak]
```

If you see just one node mentioned, it's possible that your cluster hosts are not joined together.

Usually it's best practice to have your cluster nodes on private network without firewall for communication among them. Firewall could be enabled just on public access point to your network instead. If for some reason you still need to have firewall enabled on cluster nodes, you will need to open some ports. Default values are UDP port 55200 and multicast port 45688 with multicast address 230.0.0.4. Note that you may need more ports opened if you want to enable additional features like diagnostics for your JGroups stack. Red Hat Single Sign-On delegates most of the clustering work to Infinispan/JGroups. For more information, see [JGroups](#) in the *JBoss EAP Configuration Guide*.

## CHAPTER 9. SERVER CACHE CONFIGURATION

Red Hat Single Sign-On has two types of caches. One type of cache sits in front of the database to decrease load on the DB and to increase overall response times by keeping data in memory. Realm, client, role, and user metadata is kept in this type of cache. This cache is a local cache. Local caches do not use replication even if you are in the cluster with more Red Hat Single Sign-On servers. Instead, they only keep copies locally and if the entry is updated an invalidation message is sent to the rest of the cluster and the entry is evicted. There is separate replicated cache **work**, which task is to send the invalidation messages to the whole cluster about what entries should be evicted from local caches. This greatly reduces network traffic, makes things efficient, and avoids transmitting sensitive metadata over the wire.

The second type of cache handles managing user sessions, offline tokens, and keeping track of login failures so that the server can detect password phishing and other attacks. The data held in these caches is temporary, in memory only, but is possibly replicated across the cluster.

This chapter discusses some configuration options for these caches for both clustered and non-clustered deployments.

### Note

More advanced configuration of these caches can be found in the [Infinispan](#) section of the *JBoss EAP Configuration Guide*.

### 9.1. EVICTION AND EXPIRATION

There are multiple different caches configured for Red Hat Single Sign-On. There is a realm cache that holds information about secured applications, general security data, and configuration options. There is also a user cache that contains user metadata. Both caches default to a maximum of 10000 entries and use a least recently used eviction strategy. Each of them is also tied to an object revisions cache that controls eviction in a clustered setup. This cache is created implicitly and has twice the configured size. There are also separate caches for user sessions, offline tokens, and login failures. These caches are unbounded in size as well.

The eviction policy and max entries for these caches can be configured in the *standalone.xml*, *standalone-ha.xml*, or *domain.xml* depending on your [operating mode](#).

#### non-clustered

```
<subsystem xmlns="urn:jboss:domain:infinispan:4.0">
  <cache-container name="keycloak" jndi-name="infinispan/Keycloak">
    <local-cache name="realms">
      <eviction max-entries="10000" strategy="LRU"/>
    </local-cache>
    <local-cache name="users">
      <eviction max-entries="10000" strategy="LRU"/>
    </local-cache>
    <local-cache name="sessions"/>
    <local-cache name="offlineSessions"/>
    <local-cache name="loginFailures"/>
    <local-cache name="work"/>
    <local-cache name="authorization">
      <eviction strategy="LRU" max-entries="100"/>
    </local-cache>
  </cache-container>
</subsystem>
```

```

    </local-cache>
    <local-cache name="keys">
      <eviction strategy="LRU" max-entries="1000"/>
      <expiration max-idle="3600000"/>
    </local-cache>
  </cache-container>

```

## clustered

```

<subsystem xmlns="urn:jboss:domain:infinispan:4.0">
  <cache-container name="keycloak" jndi-name="infinispan/Keycloak">
    <transport lock-timeout="60000"/>
    <local-cache name="realms">
      <eviction max-entries="10000" strategy="LRU"/>
    </local-cache>
    <local-cache name="users">
      <eviction max-entries="10000" strategy="LRU"/>
    </local-cache>
    <distributed-cache name="sessions" mode="SYNC" owners="1"/>
    <distributed-cache name="offlineSessions" mode="SYNC"
owners="1"/>
    <distributed-cache name="loginFailures" mode="SYNC" owners="1"/>
    <distributed-cache name="authorization" mode="SYNC" owners="1"/>
    <replicated-cache name="work" mode="SYNC"/>
    <local-cache name="keys">
      <eviction max-entries="1000" strategy="LRU"/>
      <expiration max-idle="3600000"/>
    </local-cache>
  </cache-container>

```

To limit or expand the number of allowed entries simply add or edit the **eviction** element or the **expiration** element of particular cache configuration.

## 9.2. REPLICATION AND FAILOVER

The **sessions**, **offlineSessions** and **loginFailures** caches are the only caches that may perform replication. Entries are not replicated to every single node, but instead one or more nodes is chosen as an owner of that data. If a node is not the owner of a specific cache entry it queries the cluster to obtain it. What this means for failover is that if all the nodes that own a piece of data go down, that data is lost forever. By default, Red Hat Single Sign-On only specifies one owner for data. So if that one node goes down that data is lost. This usually means that users will be logged out and will have to login again.

You can change the number of nodes that replicate a piece of data by change the **owners** attribute in the **distributed-cache** declaration.

### owners

```

<subsystem xmlns="urn:jboss:domain:infinispan:4.0">
  <cache-container name="keycloak" jndi-name="infinispan/Keycloak">
    <distributed-cache name="sessions" mode="SYNC" owners="2"/>
    ...

```

Here we've changed it so at least two nodes will replicate one specific user login session.

### Tip

The number of owners recommended is really dependent on your deployment. If you do not care if users are logged out when a node goes down, then one owner is good enough and you will avoid replication.

## 9.3. DISABLING CACHING

To disable the realm or user cache, you must edit the `standalone.xml`, `standalone-ha.xml`, or `domain.xml` file in your distribution. The location of this file depends on your [operating mode](#). Here's what the config looks like initially.

```
<spi name="userCache">
  <provider name="default" enabled="true"/>
</spi>

<spi name="realmCache">
  <provider name="default" enabled="true"/>
</spi>
```

To disable the cache set the **enabled** attribute to false for the cache you want to disable. You must reboot your server for this change to take effect.

## 9.4. CLEARING CACHES AT RUNTIME

To clear the realm or user cache, go to the Red Hat Single Sign-On admin console Realm Settings → Cache Config page. On this page you can clear the realm cache, the user cache or cache of external public keys. This will clear the caches for all realms and not only the selected realm.
